Abstract

In interconnection networks, matching preclusion is a measure of robustness when there is a link failure. Let G be a graph of even order. The matching preclusion number $mp(G)$ is defined as the minimum number of edges whose deletion results in a subgraph without perfect matchings. Many interconnection networks are super matched, that is, their optimal matching preclusion sets are precisely those induced by a single vertex. In this paper, we obtain general results of vertex-transitive graphs including many known networks. A k -regular connected vertex-transitive graph has matching preclusion number k and is super matched except for six classes of graphs. From this many previous results can be directly obtained and matching preclusion for some other networks, such as folded k -cubes, Hamming graphs and halved k -cubes, are derived.

Keywords. Matching Preclusion; Networks; Vertex-transitive Graphs.

2010 Mathematics Subject Classification. 94C15, 05C70.

1 Introduction

A *network* (or *graph*) is a collection of points or nodes, called *vertices*, and a collection of links, called *edges*, each connecting two nodes. The number of vertices of a graph G is its *order*, written $|G|$; its number of edges is denoted by $||G||$. We use $V(G)$ and $E(G)$ denote the vertex-set and edge-set of G respectively. Throughout this article, all graphs are assumed to be connected and of even order. The matching preclusion, viewed as a measure of the robustness of graphs, of many networks has been investigated. By summarizing these results, we can see that almost all the networks considered are vertex-transitive and surprisingly, their matching preclusion almost act in the same way. A natural question arises: What does the matching preclusion of vertex-transitive graphs act? More precisely, can we obtain a unified property on the matching preclusion of vertex-transitive graphs?

A *perfect matching* in a graph is a set of edges such that every vertex is incident with exactly one edge in this set. For $S \subseteq E(G)$, if $G - S$ has no perfect matchings, where $G - S$ denotes the subgraph of G by deleting S from it, then we call S a *matching preclusion set*. The *matching preclusion number*

[†]The corresponding author.

of a graph G , denoted by $mp(G)$, is the minimum cardinality among all matching preclusion sets. Correspondingly, the matching preclusion set attaining the matching preclusion number is called an *optimal matching preclusion set* (or in short, *optimal solution*). The concept of matching preclusion was introduced by Brigham et al. for “measuring the robustness of a communications network graph which is a model for the distributed algorithm that require each node of it to be matched with a neighboring partner node ”[1].

Until now, the matching preclusion numbers of lots of networks (graphs) have been computed, such as Petersen graph, hypercube, complete graphs and complete bipartite graphs [1], Cayley graphs generalized by transpositions and (n, k) -star graphs [2], augmented cubes [3], (n, k) -buddle-sort graphs [6], tori and related Cartesian products [8], burnt pancake graphs [10], balanced hypercubes [12], restricted HL-graphs and recursive circulant $G(2^m, 4)$ [15], and k -ary n -cubes [19]. Their optimal solutions have been also classified.

By deleting the edges incident with a given vertex in a graph, the resulting subgraph has no perfect matchings. Hence the matching preclusion number is bounded by the minimum degree.

Theorem 1.1 ([2]). *Let G be a graph of even order. Then $mp(G) \leq \delta(G)$, where $\delta(G)$ is the minimum degree of G .*

In a network, a vertex with a special matching vertex after edge failure any time implies that tasks running on a fault vertex can be shifted onto its matching vertex. Thus under this fault assumption, larger $mp(G)$ signifies higher fault tolerance. Fortunately, matching preclusion numbers of many regular interconnection networks of degree k attained the maximum value, the minimum degree k . Moreover, the optimal solutions are precisely those induced by a single vertex except the ones with small order. Formally, we call the optimal solution incident with a single vertex a *trivial optimal solution* (*non-trivial optimal solution* otherwise) and the graphs with all optimal solutions trivial *super matched*. Generally, in the event of a random link failure, it is very unlikely that all of the links incident to a single vertex fail simultaneously. From this point of view, that a graph is super matched implies that it has higher fault tolerance.

Recalling that the networks whose matching preclusion have been considered, we can see that many of them are vertex-transitive graphs. A graph H is called *vertex-transitive* if for any two vertices x, y in $V(H)$, there exists an automorphism φ of H such that $\varphi(x) = y$. From the known results, we can see that almost all of them are super matched. Fortunately, we obtain that almost all vertex-transitive graphs have such properties, too. Precisely, we get the following result, in which, $Z_{4n}(1, 4n, 2n)$ stands for the Cayley graph on Z_{4n} , the additive group modulo $4n$, with the generating set $S = \{1, 4n - 1, 2n\}$. $Z_{4n+2}(2, 4n, 2n + 1)$ and $Z_{4n+2}(1, 4n + 1, 2n, 2n + 2)$ are defined similarly.

Theorem 1.2. *A k -regular connected vertex-transitive graph G of even order is super matched if and only if it doesn't contain cliques of size k when k is odd and $k \leq |G| - 2$ or it is not isomorphic to a cycle of length at least six or $Z_{4n}(1, 4n - 1, 2n)$ or $Z_{4n+2}(2, 4n, 2n + 1)$ or $Z_{4n+2}(1, 4n + 1, 2n, 2n + 2)$ or the Petersen graph.*

This article is organized as follows. In Section 2, we will analyse some structural properties of

vertex-transitive graphs. In Section 3, we present the proof of Theorem 1.2. In Section 4, we make a conclusion and several applications to obtain the matching preclusion of some networks.

2 Preliminaries

In this section, we shall present several results that will be used later. An edge set $S \subseteq E(G)$ is called an *edge-cut* if there exists a set $X \subseteq V(G)$ such that S is the set of edges between X and $V(G) \setminus X$. The *edge-connectivity* $\lambda(G)$ of G is the minimum cardinality over all edge-cuts of G . Mader proved the following result.

Lemma 2.1 ([13]). *If G is a k -regular connected vertex-transitive graph, then $\lambda(G) = k$.*

The following lemma makes a step further by characterizing the minimum edge-cuts of vertex-transitive graphs, where a clique of a graph G is a subset of its vertices such that every two vertices in the subset are connected by an edge.

Theorem 2.2 ([11], Lemma 5.5.26). *Let G be a k -regular connected vertex-transitive graph. Then $\lambda(G) = k$ and either*

- (i) *every minimum edge-cut of G is the star of a vertex, or*
- (ii) *G arises from a (not necessarily simple) vertex- and edge-transitive k -regular graph G_0 by a k -clique (cliques of size k) insertion at each vertex of G_0 . Moreover, every minimum edge-cut of G is the star of a vertex of G or a minimum edge-cut of G_0 .*

The following corollary that will be used in Section 3 follows immediately. An edge-cut is called *trivial* if it isolates a vertex and *non-trivial* otherwise.

Corollary 2.3. *For a k -regular connected vertex-transitive graph G , every k -edge-cut (an edge-cut of size k) is either trivial or the deletion of it results in two components, and each component's vertices are partitioned into several k -cliques.*

For a k -regular graph G , if every minimum edge-cut of it is trivial, then we say it is *super-edge-connected* (or simply *super- λ*). For vertex-transitive graphs, J. Meng has presented a characterization with respect to the cliques.

Theorem 2.4 ([14]). *Let G be a k -regular connected vertex-transitive graph which is neither a complete graph nor a cycle. Then G is super- λ if and only if it does not contain k -cliques.*

Theorem 2.4 is used to characterize the structure of 3-regular connected non-bipartite vertex-transitive graphs with respect to the length of the minimum odd cycles. As we will see, minimum odd cycles play a crucial role in the following proof in this section. Here we make a convention that is suitable throughout this paper. For a cycle drawn on the plane without crossings, let $a, b \in V(C)$, denote P_{ab} by the path of C from a to b along a clockwise direction. A cycle C is called a *minimum odd cycle* if $|C|$ is odd and it is the minimum among lengths of all odd cycles. For a minimum odd cycle, we usually say it is *minimum*. The following two results (Lemmas 2.5 and 2.6) will be used to prove Lemma 2.7, which play an important role in the proof of Theorem 1.2 in the next section.

Lemma 2.5. *Let G be a non-bipartite connected vertex-transitive graph of even order and C be a minimum odd cycle in G with $|C| \geq \frac{|G|}{2}$. If G is not isomorphic to K_4 or K_6 , then any vertex in $V(G) \setminus V(C)$ is adjacent to at most two vertices in $V(C)$. If in addition, a vertex $v \in V(G) \setminus V(C)$ is adjacent to two vertices u and w in $V(C)$, then either P_{uw} or P_{wu} in C is of length 2 and further G has a quadrangle containing v, u and w .*

Proof. We first draw C on the plane without crossings. Suppose by the contrary that there exists a vertex $v \in V(G) \setminus V(C)$ with at least three neighbors in $V(C)$. Let a, b and c be three neighbors of v in $V(C)$ and they are placed in C in a successive order along the clockwise direction. Since $\|P_{ab}\| + \|P_{bc}\| + \|P_{ca}\| = \|C\|$ is odd, at least one of $\|P_{ab}\|$, $\|P_{bc}\|$ and $\|P_{ca}\|$ is odd, we may assume that $\|P_{ab}\|$ is odd. Hence $\|P_{bc}\| + \|P_{ca}\|$ is even. If $\|P_{bc}\| + \|P_{ca}\| = 2$, then vac is an odd cycle of length three, so is C since C is minimum. Further, $|G| \leq 2\|C\| = 6$, we can easily check that G is isomorphic to K_4 or K_6 , which contradicts the hypothesis. If $\|P_{bc}\| + \|P_{ca}\| \geq 4$, then $E(P_{ab}) \cup \{va, vb\}$ induces an odd cycle of smaller length than C , which contradicts that C is minimum.

By the above arguments, any vertex in $V(G) \setminus V(C)$ is adjacent to at most two vertices in $V(C)$. If $v \in V(G) \setminus V(C)$ is adjacent to exactly two vertices u and w in $V(C)$, then by $\|P_{uw}\| + \|P_{wu}\| = \|C\|$ is odd, either $\|P_{uw}\|$ or $\|P_{wu}\|$ is even. We may assume that $\|P_{uw}\|$ is even. Further, the edges of P_{wu} and $\{vu, vw\}$ form an odd cycle of length at least $\|C\|$. Hence $\|P_{uw}\| = 2$ and $E(P_{uw}) \cup \{vu, vw\}$ induces a quadrangle containing v, u and w . $\square$

For a graph G , let the girth (odd girth) of G , denoted by $g(G)$ ($g_o(G)$), be the length of a shortest cycle (odd cycle) in G . We say two quadrangles in G *adjacent* if they share vertices or edges.

Lemma 2.6. *Let G be a 3-regular connected non-bipartite vertex-transitive graph of girth 4. If G has adjacent quadrangles, then it is isomorphic to $Z_{4n}(1, 4n-1, 2n)$ or $Z_{4n+2}(2, 4n, 2n+1)$ with $n \geq 2$. Otherwise $g_o(G) \leq \frac{|G|}{2}$.*

Proof. By Theorem 2.1, G is 3-edge-connected. Further, since G is of girth 4, that is, G does not contain 3-cliques (triangles), every 3-edge-cut is trivial by Theorem 2.4.

If G has adjacent quadrangles q_1 and q_2 , then by the 3-regularity of G , q_1 and q_2 should share at least one edge. If q_1 and q_2 share exactly three edges, then we obtain multiple edges, contradicting that G is simple; If q_1 and q_2 share exactly two edges, let H be the subgraph of G induced by the edges of q_1 and q_2 , then H has exactly three vertices of degree 2 and the others of degree 3. Since every 3-edge-cut of G is trivial, we obtain that the three degree-2 vertices in H are adjacent to a common neighbor, that is, G is $K_{3,3}$, which contradicts that G is non-bipartite. By the above arguments, q_1 and q_2 should share exactly one edge, that is, G contains $K_2 \times P_3$ as a subgraph, where ‘ $\times$ ’ means the Cartesian product of graphs and P_3 denotes a path P_m with $m = 3$ vertices. Let $K_2 \times P_m$ with $m \geq 3$ be a subgraph of G with m maximum (see Figure 1 (left)). For the four vertices x_1, y_1, x_m and y_m , if any two of them are adjacent to each other, then the remaining two of them are adjacent by the 3-connectivity of G , this implies that G is isomorphic to $Z_{2m}(1, 2m-1, m)$ when m is even or $Z_{2m}(2, 2m-2, m)$ when m is odd with $m \geq 3$ (see Figure 1 (the middle and right ones)). If no two of them are adjacent to each other, then we may suppose that x_m is adjacent to x_{m+1} and y_m

is adjacent to y_{m+1} . By the vertex-transitivity of G , we know that there are at least two adjacent quadrangles containing y_m . Then by a simple check, we can obtain that x_{m+1} and y_{m+1} should be adjacent, then we find a subgraph $K_2 \times P_{m+1}$ in G , which contradicts our selection.

Figure 1.

If G does not contain adjacent quadrangles, then every vertex lies in exactly one quadrangle. Suppose to the contrary that $g_o(G) \geq \frac{|G|}{2} + 1$. Let C be a minimum odd cycle with length $g_o(G)$. We shall obtain a contradiction by proving that there are at least $|C|$ vertices in $V(G) \setminus V(C)$. Since G is not K_4 or K_6 (by the hypothesis that G is of girth 4) and C is minimum, by Lemma 2.5, any vertex in $V(G) \setminus V(C)$ is adjacent to at most two vertices in $V(C)$.

Since every vertex lies in a quadrangle and C is minimum, each quadrangle containing vertices in $V(C)$ can only contain one or two edges in C . Denote G' by the subgraph of G induced by the edges in C and the quadrangles having a non-empty intersection with C (see Figure 2 (left)). For any vertex $a \in V(C)$, if it is of degree 2 in G' , then we claim that all its neighbors in G cannot lie entirely in $V(G')$. Suppose not. Since C is minimum, C has no chords, we obtain the two structures shown in Figure 2 (the middle and right ones). For each case, by Lemma 2.5, v , a and b lie in a quadrangle. Then we obtain two adjacent quadrangles, a contradiction.

Figure 2.

In G' , for all the degree-2 vertices in $V(C)$, we collect the edges incident to them in $E(G) \setminus E(G')$, denoted by F (the bold edges in Figure 3 (left)). We claim that F is a matching. If not, then we obtain a vertex v adjacent to two vertices a and b in $V(C)$. By Lemma 2.5, v , a and b lie in a quadrangle. Then we see that both a and b lie in two quadrangles, a contradiction.

Denote G'' by the subgraph induced by $E(G') \cup F$ in G , and denote the set of degree-1 vertices in G'' be A . It is obvious that $|A| = |F|$. We are going to show that there are at least $|A|$ vertices in

$V(G) \setminus V(G'')$. If so, then by a simple computation (for the vertices in $V(C)$ lying in the quadrangles sharing exactly one edge with $E(C)$, there is the same number of vertices in the quadrangles in $V(G) \setminus V(C)$; for the vertices in $V(C)$ lying in the quadrangles sharing exactly two edges with $E(C)$, by counting the vertices in quadrangles not in $V(C)$, the vertices contained in F not in $V(C)$ and the vertices in $V(G) \setminus V(G'')$, we obtain the same conclusion too), there are at least $|C|$ vertices in $V(G) \setminus V(C)$, which contradicts that C is of length at least $\frac{|G|}{2} + 1$.

Figure 3.

We are left to prove that there are at least $|A|$ vertices in $V(G) \setminus V(G'')$. For any vertex $v \in A$, let the quadrangle containing it be Q_v . If Q_v contains three vertices in $V(G) \setminus V(G'')$, then any vertex u in A other than v cannot be adjacent to any vertex in this quadrangle (otherwise, Q_u and Q_v are adjacent, a contradiction), and we count three for $V(G) \setminus V(G'')$; If the quadrangle containing it contains exactly two vertices g and h in $V(G) \setminus V(G'')$ (see the middle one in Figure 3), similarly, any vertex in A other than e and f can not be adjacent to g and h (if there does exist such a vertex w , then by considering the quadrangle containing w , we obtain two adjacent quadrangles, a contradiction), then we count two for these two vertices e and f in A . Moreover, since C is a minimum odd cycle, by a similar argument as above, we can deduce that $||P_{cd}|| = 3$ or $||P_{dc}|| = 3$; If the quadrangle containing it contains at most one vertex in $V(G) \setminus V(G'')$ (see the right one in Figure 3), then we can deduce that $||P_{bu}|| = ||P_{ua}|| = 3$. By substituting the edges in P_{ba} in C with the bold edges, we obtain an odd cycle of length smaller than C , which contradicts that C is minimum. Therefore, there are at least $|A|$ vertices in $V(G) \setminus V(G'')$. This completes the proof. $\square$

Now everything is ready to prove the following key lemma which characterizes the vertex-transitive graphs with provided structure.

Lemma 2.7. *Let G be a k -regular connected non-bipartite vertex-transitive graph. Let $S \subseteq V(G)$ with $|S| = |\overline{S}| + 2$, where $\overline{S} = V(G) \setminus S$, and $\overline{S}$ is an independent set of G . Then G is isomorphic to $Z_{4n+2}(1, 4n+1, 2n, 2n+2)$ or $Z_{4n}(1, 4n-1, 2n)$ or $Z_{4n+2}(2, 4n, 2n+1)$ or the Petersen graph.*

Proof. Obviously, $\overline{S} \neq \emptyset$. Let C be a minimum odd cycle and $l = |C|$.

Claim 1. $l = g_o(G) \geq \frac{|G|}{2}$.

Suppose that there are n_l minimum odd cycles in G and each vertex is contained in v_l minimum odd cycles. Since $G[\overline{S}]$ is empty, each minimum odd cycle contains at most $\frac{l-1}{2}$ vertices in $\overline{S}$ and at

least $\frac{l+1}{2}$ vertices in S . By counting the number (repeated by re-number calculation) of minimum odd cycles passing through the vertices in $\overline{S}$, we have

$$v_l \times |\overline{S}| \leq \frac{l-1}{2} n_l.$$

Similarly for S , we have

$$v_l \times |S| \geq \frac{l+1}{2} n_l.$$

Combining the above two inequalities with $|S| = |\overline{S}| + 2$, we have $v_l \geq \frac{n_l}{2}$. Consequently, by counting the number of times (repeated by re-number calculation) that the minimum odd cycles passing through all the vertices in G , we obtain that $n_l \times l = v_l \times |G| \geq \frac{n_l}{2} \times |G|$, which implies $l \geq \frac{|G|}{2}$. So Claim 1 holds.

Now we show that only vertex-transitive graphs with small k satisfy the conditions in the lemma.

Claim 2. $3 \leq k \leq 4$.

We first show that $k \geq 3$. If not, then G is an odd cycle, which contradicts that G is of even order ($|G| = 2|\overline{S}| + 2$).

Next we will show $k \leq 4$. Since C is minimum, C has no chords. So there are $l(k-2)$ edges between $V(C)$ and $\overline{V(C)} = V(G) \setminus V(C)$. If G is isomorphic to K_4 , then $k = 3 \leq 4$. G is not isomorphic to K_6 . Otherwise for any $S \subseteq V(G)$ with $|S| = |\overline{S}| + 2$, we have $|\overline{S}| = 2$ and hence $G[\overline{S}]$ is not empty, which contradicts the hypothesis. Hence we only need to consider that G is not isomorphic to K_4 or K_6 . By Lemma 2.5, any vertex in $\overline{V(C)}$ can only be adjacent to at most two vertices in $V(C)$. So there are at least $\frac{l(k-2)}{2}$ vertices in $\overline{V(C)}$.

By Claim 1, $|C| = l \geq \frac{|G|}{2}$. On one hand, $|\overline{V(C)}| \geq \frac{l(k-2)}{2} \geq \frac{|G| \times (k-2)}{4}$. On the other hand, $|\overline{V(C)}| = |G| - l \leq \frac{|G|}{2}$. Combining these two inequalities, that is, $\frac{|G| \times (k-2)}{4} \leq |\overline{V(C)}| \leq \frac{|G|}{2}$, we have $k \leq 4$.

In the following, we divide the remaining proof into two cases: $k = 4$ and $k = 3$.

Case 1. $k = 4$.

Figure 4. $Z_{4n+2}(1, 4n+1, 2n, 2n+2)$ and the labeling of it.

For any minimum odd cycle C , by the above proof, $\frac{|G|}{2} \leq \frac{|G| \times (k-2)}{4} \leq |\overline{V(C)}| \leq \frac{|G|}{2}$. Thus all

equalities hold, that is, $l = \frac{|G|}{2}$ and every vertex in $\overline{V(C)}$ is adjacent to exactly two vertices in $V(C)$. So every vertex in $\overline{V(C)}$ is of degree 2 in $G[\overline{V(C)}]$, the subgraph of G induced by $\overline{V(C)}$, and hence $G[\overline{V(C)}]$ is a union of disjoint cycles. By $|\overline{V(C)}| = |C| = l$ and C is minimum, $G[\overline{V(C)}]$ is indeed a minimum odd cycle. Therefore, we conclude that the deletion of any minimum odd cycle results in another minimum odd cycle.

Let C_1 be a minimum odd cycle and C_2 be the minimum odd cycle of G by deleting $V(C_1)$ from it, we draw C_1 and C_2 on the plane as in Figure 4. Suppose that $a \in V(C_2)$ is adjacent to b and c in $V(C_1)$. Then by Lemma 2.5, either P_{cb} or P_{bc} in C_1 is of length 2, we may assume that P_{bc} . The edges of P_{cb} in C_1 , ca and ab form a minimum odd cycle. By deleting it, we obtain another minimum odd cycle. That is, d should be adjacent to e and f , where e and f are neighbors of a in C_2 . By continuing this process repeatedly, we obtain G is isomorphic to the graph shown in Figure 4 (left), by labeling it as shown in Figure 4 (right), we can see G is isomorphic to $Z_{4n+2}(1, 4n+1, 2n, 2n+2)$ for some integer n .

Case 2. $k = 3$.

For $g(G) = 3$ or 5 , Claim 1 implies that $|G| \leq 2l \leq 10$. Read and Wilson [17] have enumerated all connected cubic vertex-transitive graphs on 34 and fewer vertices, from which, we deduce that all connected non-bipartite cubic vertex-transitive graphs of at most 10 vertices are either $Z_{4n}(1, 4n-1, 2n)$ or $Z_{4n+2}(2, 4n, 2n+1)$ with $n = 1$ and 2 , or the Petersen graph. We are done.

For $g(G) = 4$, G has adjacent quadrangles. Otherwise, $|G| = 4m$ for some integer m . But Claim 1 and Lemma 2.6 imply $l = \frac{|G|}{2}$ and $|G| = 4t + 2$ for some integer t , a contradiction. By Lemma 2.6, G is isomorphic to a graph in $Z_{4n}(1, 4n-1, 2n)$ or $Z_{4n+2}(2, 4n, 2n+1)$ for some integer n .

Claim 3. $g(G) \leq 5$. Suppose to the contrary that $g(G) \geq 6$.

There is no vertex in $\overline{V(C)}$ adjacent to two vertices in $V(C)$. If not, then by Lemma 2.5, we obtain a quadrangle, a contradiction. Thus the edges sending out from $V(C)$ form a matching. That is, there are at least l vertices in $\overline{V(C)}$. By Claim 1, $l \geq \frac{|G|}{2}$, we obtain $l = \frac{|G|}{2}$. Now, we focus on the graph $G' = G[\overline{V(C)}]$. Since $|G'|$ is odd and each vertex in G' is of degree 2, G' is a union of disjoint cycles. Further, because l is the length of minimum odd cycles, G' is a cycle of length l .

By the above arguments, we conclude that

(i) $V(G)$ can be decomposed into two parts V_1 and V_2 such that both $G[V_1]$ and $G[V_2]$ are minimum odd cycles.

(ii) The deletion of any minimum odd cycle from G results in a minimum cycle, too.

Since $\overline{S}$ is an independent set of G , by a simple computation, we have that $G[S]$ contains three edges, and every odd cycle contains either one or three edges in $G[S]$. Hence the following holds.

(iii) Every minimum odd cycle contains exactly one edge in $G[S]$. (Otherwise, suppose there is a minimum odd cycle containing three edges in $G[S]$. By (ii), the deletion of it results in a minimum odd cycle which contains no edges in $G[S]$, a contradiction.)

Denote the three edges in $G[S]$ by e_1, e_2 and e_3 . Then by (i) and (iii), we may assume that C_1 and C_2 are two vertex-disjoint minimum odd cycles containing e_1 and e_2 respectively. Also by (iii), e_3 does not lie in C_1 or C_2 . For the simplicity of description, we color the vertices in S white and

the vertices in $\overline{S}$ black. So two white vertices are adjacent if and only if they are the end-vertices of some e_i , for $i = 1, 2$ or 3 . There are three cases to consider.

Figure 5. The illustration of proof of Case 2.

Subcase 2.1. e_1 , e_2 and e_3 are independent.

We draw C_1 and C_2 on the plane as shown in Figure 5 (left). Let c be an end-vertex of e_1 , b the neighbor of c in $V(C_2)$ and a the end-vertex of e_3 in $V(C_2)$. We may assume that e_2 lies on P_{ab} in C_2 . Otherwise we may redraw C_2 by interchanging P_{ab} and P_{ba} . The union of the edges of P_{ab} in C_2 , e_3 , the edges of P_{dc} in C_1 and cb form a cycle, denoted by C_3 . Since C_3 contains three edges in $G[S]$, it is an odd cycle of length at least $l + 2$. Simultaneously, the union of the edges of P_{ba} in C_2 , e_3 , the edges of P_{cd} in C_1 and cb form a cycle, denoted by C_4 . Since C_4 contains exactly one edge in $G[S]$, it is an odd cycle of length at least l . Clearly, we have $|C_1| + |C_2| + 4 = |C_3| + |C_4|$. That is, $|C_3| + |C_4| = 2l + 4$. Hence $l + 2 \leq |C_3| \leq l + 4$ by $|C_4| \geq l$.

Now we show that C_3 has no chords. Suppose by the contrary that C_3 has a chord. Then by using the chord and $E(C_3)$, we get two cycles, one is of odd length denoted by C_5 and one is of even length. By $g \geq 6$, the one with even length is of length at least 6 and C_5 is of length at least l . Since the sum of the lengths of these two cycles is at most $l + 6$, we obtain that C_5 is a minimum odd cycle and the other even cycle is of length 6. By deleting $V(C_5)$ from G , we can see the resulting graph has at least one vertex in $\{a, b, c, d\}$ of degree 3 and further cannot be a cycle, which contradicts (ii).

Since C_3 has no chords and also C_2 has no chords, the end-vertices of e_2 are adjacent to vertices in $V(C_1) \setminus V(C_3)$, denoted by e and f . Then the bold edges in Figure 5 (left) form a new cycle C_6 . Since C_6 contains only one edge in $G[S]$, it is an odd cycle. Recall that two white vertices are adjacent if and only if they are the end-vertices of some e_i , P_{ef} in C_1 are of length at least five. $||P_{ef}| + |P_{fe}|| = l$, so for C_1 , by substituting the edges in P_{ef} with the bold edges eg , e_2 and hf , we obtain that C_6 is an odd cycle of length smaller than l , a contradiction.

Subcase 2.2. e_1 , e_2 and e_3 form a path of length three (see Figure 5 (middle)).

Similarly to Subcase 2.1, we may assume that e_1 , e_2 and e_3 are placed exactly like in Figure 5 (middle). Suppose that c is adjacent to a vertex $a \in V(C_2)$. We consider the cycle (the bold edges in Figure 5 (middle)) consisting of the edges of P_{da} in C_2 , ac , e_1 and e_3 . This cycle, denoted by C_7 , contains exactly three edges in $G[S]$, so it is an odd cycle and of length at least $l + 2$ by (iii). Hence P_{da} in C_2 is of length at least $l - 1$ and further da is an edge. Then the four edges da , ac , e_1 , e_3 form

a quadrangle, which contradicts that $g(G) \geq 6$.

Subcase 2.3. e_1, e_2 and e_3 form a union of an independent edge and a path of length two (see Figure 5 (right)).

Similarly to Subcase 2.1, we may assume that e_1, e_2 and e_3 are placed exactly like in Figure 5 (right). Suppose that the neighbor of g in $V(C_2)$ be b and the neighbor of a in $V(C_2)$ be c . Let C_8 be the cycle formed by the edges of P_{db} in C_2 , bg , the edges of P_{hg} in C_1 and hd . By the similar argument as for C_3 in Subcase 2.1, we know that C_8 has no chords. Hence c lies in P_{bd} in C_2 . Let C_9 (the bold edges in Figure 5 (right)) be the cycle formed by the edges of P_{bc} in C_2 , ca , e_1 and gb . Since P_{cb} in C_2 is of length at least three, by a similar argument as above, we get that C_9 is a minimum odd cycle. By (ii), the deletion of C_9 results in a minimum odd cycle having no vertices of degree 3. Hence ha is an edge, but h and a receive the same white color, a contradiction. $\square$

3 Matching Preclusion

In this section, we shall prove Theorem 1.2. We first present the Plesník's Theorem which is used to estimate the lower bound of matching preclusion number.

Theorem 3.1 ([11]). *If G is a k -regular $(k-1)$ -edge-connected graph of even order, then $G-F$ has a perfect matching for every $F \subseteq E(G)$ with $|F| \leq k-1$.*

For the classification of optimal solutions, Hall's Theorem (for the bipartite case) and Tutte's Theorem (for the non-bipartite case) are used.

Theorem 3.2 (Hall's Theorem [16]). *Let G be a bipartite graph with bipartition W and B . Then G has a perfect matching if and only if $|W| = |B|$ and for any $U \subseteq W$, $|N(U)| \geq |U|$ holds.*

Theorem 3.3 (Tutte's Theorem [18]). *A graph G has a perfect matching if and only if $c_o(G-U) \leq |U|$ for any $U \subseteq V(G)$, where $c_o(G-U)$ is the number of odd components of $G-U$.*

Now we are ready to prove Theorem 1.2. Note that for the classification of optimal solutions of the bipartite vertex-transitive graphs, the authors [4] presented a sufficient condition for regular bipartite graphs to be super matched with respect to the concept "super edge-connected", the method here is similar.

Proof of Theorem 1.2. By Lemma 2.1, G is k -edge-connected. Then by Theorem 3.1, $mp(G) \geq k$. Combining this with Theorem 1.1, we obtain $mp(G) = k$. We are left to classify the optimal solutions.

Necessity. We prove by contradiction that if G is isomorphic to one of the six classes, then it has a non-trivial optimal solution.

(a) G contains a clique S of size k when k is odd and $k \leq |G| - 2$. Since $k \leq |G| - 2$, $\overline{S}$ consists of at least two vertices. The edges between S and $\overline{S}$ is a non-trivial optimal solution.

(b) G is isomorphic to a cycle of length at least six. Suppose that $G = v_1v_2 \dots v_nv_1$ with $n \geq 6$. Then the edge set $\{v_1v_2, v_4v_5\}$ forms a non-trivial optimal solution.

(c) G is isomorphic to $Z_{4n}(1, 4n-1, 2n)$. Pick $F = \{12, 1(2n+1), (2n+1)2n\}$ and $S = \{2i+1 | 1 \leq i \leq n-1\} \cup \{2i | n+1 \leq i \leq 2n\}$. Then $G - F - S$ consists of $2n+1$ isolated vertices. By $|S| = 2n-1$ and Tutte's Theorem, $G - F$ has no perfect matchings. Hence F is a non-trivial optimal solution.

(d) G is isomorphic to $Z_{4n+2}(2, 4n, 2n+1)$. Let $F = \{(4n+1)1, 1(2n+2), (2n+2)(2n+4)\}$ and $S = \{4i-1 | 1 \leq i \leq n\} \cup \{2n+2+4i | 1 \leq i \leq n\}$. Similarly to (c), one can check that F is a non-trivial optimal solution.

(e) G is isomorphic to $Z_{4n+2}(1, 4n+1, 2n, 2n+2)$. Make $F = \{12, 2(2n+2), (2n+2)(2n+3), (2n+3)1\}$ and $S = \{2i+1 | 1 \leq i \leq n\} \cup \{2i | n+2 \leq i \leq 2n+1\}$. Similarly to (c), one can check that F is a non-trivial optimal solution.

(f) G is isomorphic to the Petersen graph. Let F be the set of three bold edges and S the set of bold vertices as shown in Figure 6. Similarly to (c), one can show F is a non-trivial optimal solution.

Figure 6. The Petersen graph is not super matched.

Sufficiency. Let F be an optimal solution. Then $|F| = mp(G) = k$ and $G - F$ has no perfect matchings. We shall show that F isolates a singleton. There are two cases to consider.

Case 1. G is bipartite.

We are to show that F is an edge-cut. Assume that W and B are the bipartition of G . By Hall's theorem, there exists $S \subseteq W$ such that $|N_{G-F}(S)| \leq |S| - 1$. On the other hand, since F is a matching preclusion set with the smallest cardinality, for each edge $e \in F$, $G - F + e$ has perfect matchings and also by Hall's Theorem, $|N_{G-F+e}(S)| \geq |S|$ holds. Note that by adding one edge e to $G - F$, the neighborhood of S increases at most one vertex. Hence $|N_{G-F+e}(S)| \leq |N_{G-F}(S)| + 1$.

Combining the above three inequations, we obtain that $|S| = |N_{G-F}(S)| + 1$. Denote $S' = N_{G-F}(S)$. The edges sending out from S are divided into two parts: One goes into F and one goes into S' . Thus S sends exactly $k|S| - |F| = k|S| - k$ edges to S' . Since $|S'| = |S| - 1$, there are no edges connecting S' to $W - S$. This implies that F is an edge-cut.

If $k = 1$, then G is isomorphic to K_2 and G is super matched; If G is a cycle of length four, then G is super matched; If $k \geq 2$, then since G is bipartite, G is triangle-free, that is, G is not isomorphic to a complete graph. By hypothesis, G is not isomorphic to a cycle of length at least six. Therefore, by Theorem 2.4, F is a trivial edge-cut, that is, F isolates a singleton.

Case 2. G is non-bipartite.

By Tutte's Theorem, there exists $S \subseteq V(G - F)$ such that $c_o(G - F - S) \geq |S| + 2$. Now we count the number N of edges between S and $\bar{S}$ in G . Since every component of $G - S$ sends out at least

k edges, we have $kc_o(G - F - S) - 2k \leq N \leq k|S|$, combining this with $c_o(G - F - S) \geq |S| + 2$, $k|S| \leq N \leq k|S|$ holds and further $c_o(G - F - S) = |S| + 2$. Hence every component sends out exactly k edges, there are no even components in $G - F - S$ and each edge in F connects two components in $G - F - S$.

If $|S| = 0$, then there are exactly two (odd) components connected by the edges in F . We claim one of them is a singleton. If not, then by Corollary 2.3, G contains a k -clique with k odd and $k \leq |G| - 2$, a contradiction.

If $|S| \neq 0$, similarly, by Corollary 2.3, each component is a singleton. Consequently, G satisfies the condition in Lemma 2.7. Hence $G \cong Z_{4n+2}(1, 4n + 1, 2n, 2n + 2)$ or $Z_{4n}(1, 4n - 1, 2n)$ or $Z_{4n+2}(2, 4n, 2n + 1)$ or the Petersen graph, contradicting the hypothesis. $\square$

Since the six classes of graphs in Theorem 1.2 are all non-bipartite except for even cycles, and $Z_{4n+2}(1, 4n + 1, 2n, 2n + 2)$, $Z_{4n}(1, 4n - 1, 2n)$, $Z_{4n+2}(2, 4n, 2n + 1)$ and the Petersen graph are of maximum degree at most four, the following two corollaries arise immediately.

Corollary 3.4. *A connected bipartite vertex-transitive graph of even order and other than a cycle is super matched.*

Corollary 3.5. *Let G be a k -regular connected vertex-transitive graph of even order and with minimum degree at least five. If it does not contain a k -clique with k odd and $k \leq |G| - 2$, then it is super matched.*

4 Conclusion and Applications

By the above argument, we can see that any connected vertex-transitive graph of even order is maximally matched. Moreover, a k -regular vertex-transitive graph of even order is super matched if and only if it doesn't contain cliques of size k when k is odd and $k \leq |G| - 2$ or it is not isomorphic to a cycle of length at least six or $Z_{4n}(1, 4n - 1, 2n)$ or $Z_{4n+2}(2, 4n, 2n + 1)$ or $Z_{4n+2}(1, 4n + 1, 2n, 2n + 2)$ or the Petersen graph. From this, the matching preclusion number and the super matchability of the following networks with even order can be obtained: (1) A complete graph or a complete bipartite graph; (2) a Cayley graph generalized by transpositions or a (n, k) -star; (3) An augmented cube; (4) An (n, k) -buddle-sort graph; (5) A tori and related Cartesian products; (6) A burnt pancake graph; (7) A balanced hypercube; (7) A recursive circulant $G(2^m, 4)$; (8) k -ary n -cubes. Note that these results have been obtained in [1], [2], [3], [6], [8], [10], [12], [15] and [19], respectively and one can easily check that the results in these papers are consistent with those obtained by applying our results. Furthermore, we can apply our results to other particular vertex-transitive networks, such as folded k -cube graphs, Hamming graphs and halved cube graphs. We just present the precise application for folded k -cubes. The others are similar and omitted.

The folded k -cube graph ($k \geq 3$), containing 2^{k-1} vertices, denoted by FQ_k may be formed by adding edges between opposite pairs of vertices in a $(k - 1)$ -hypercube graph.

Theorem 4.1. *A folded k -cube graph is super matched if and only if $k \geq 4$.*

Proof. Clearly, FQ_k is k -regular. FQ_3 is K_4 and FQ_4 is the complete bipartite graph $K_{4,4}$. By the vertex-transitivity of the k -hypercube graph, one can easily check that FQ_k is vertex-transitive. If $k = 3$, $FQ_3 = K_4$ is isomorphic to $Z_4(1, 3, 2)$, then by Theorem 1.2, FQ_3 is not super matched. If $k = 4$, FQ_4 is a bipartite graph other than a cycle, then by Corollary 3.4, it is super matched. If $k \geq 5$, then FQ_k is of minimum degree at least five and does not contain a k -clique, and by Corollary 3.5, it is super matched. $\square$

The Hamming graph $H(d, q)$ can be viewed as the Cartesian product of d complete graphs K_q .

Theorem 4.2. *A Hamming graph $H(d, q)$ with even order is super matched if and only if $(d, q) \notin \{(1, 4), (2, 2)\}$.*

The halved k -cube graph or half k -cube graph ($k \geq 3$) is the graph of the demihypercube, formed by connecting pairs of vertices at distance exactly two from each other in the k -hypercube graph. This connectivity pattern produces two isomorphic graphs, disconnected from each other, each of which is the halved k -cube graph.

Theorem 4.3. *A halved k -cube graph is super matched if and only if $k \geq 4$.*
